Branch and trunk canker on avocado was formerly attributed to *Dothiorella gregaria*, hence the name *Dothiorella* canker. So far *Botryosphaeria dothidea* (anamorph: *Fusicoccum aesculi*) is the only known species causing *Dothiorella* canker on avocado in California. Symptoms observed on avocado with *Dothiorella* canker include shoot blight and dieback, leaf scorch, fruit rot, and cankers on branches and bark (Fig. 1, 2, 3).

However, recent studies based on DNA analyses suggest greater species diversity of this pathogen group than based on morphological characteristics alone. Thus far, multiple species of *Botryosphaeriaceae* have been found to cause the typical *Dothiorella* canker (Fig 3, 4) and stem-end rot (Fig 5), leaf scorch (Fig. 6) on avocado in California. Percent recovery of *Botryosphaeria* spp. based on morphological characters ranged from 40-100% in Riverside county, 42-53% in Ventura county, 33% in Santa Barbara county, 60% in San Diego county and 32-60% in San Luis Obispo county.

Fig. 1. *Dothiorella* branch dieback and canker symptoms on Hass cv. avocado tree.

According to preliminary results from a continuing survey throughout avocado growing areas of California, multiple species of *Botryosphaeria* (*Neofusicoccum australe, B. dothidea, N. luteum, and N. parvum*) were found.

Fig. 3. *Dothiorella* perennial canker on branch

Pycnidia (overwintering structure) of *Botryosphaeriaceae* species were also observed on
old diseased avocado tree branches. Sequenced rDNA fragments (ITS1, 5.8S rDNA, ITS2, amplified with ITS4 and ITS5 primers) were compared with sequences deposited in GenBank.

Pathogenicity tests were conducted in the greenhouse on 1-year-old avocado seedlings, Hass cv., with one randomly chosen isolate from each of the Botryosphaeriaceae species noted above. Four replicate seedlings were stem-wound inoculated with a mycelial plug and covered with Parafilm. Sterile PDA plugs were applied to four seedlings as a control. Over a period of 6 months, seedlings were assessed for disease symptoms that included browning of leaf edges and shoot dieback. Mean vascular lesion lengths on stems were 64, 66, 64, and 18 mm for B. dothidea, N. parvum, N. luteum, and N. austral, respectively. Each fungal isolate was consistently reisolated from inoculated seedlings, thus completing the pathogenicity test. To our knowledge, this is the first report of N. austral, N. luteum, and N. parvum recovered from branch cankers on avocado in California.

These results are significant because Botryosphaeriaceae canker pathogens are known to enter the host plant through fresh wounds (pruning, frost, and mechanical). With high-density planting becoming more common, which requires intensive pruning, the transmission rate of these pathogens could increase in California avocado groves. The Eskalen laboratory is currently investigating control measures for dothiorella canker and stem-end rot pathogens.
